

A GENERAL NOTION OF VISIBILITY GRAPHS

MIKE DEVELIN*, STEPHEN HARTKE, AND DAVID PETRIE MOULTON

ABSTRACT. We define a natural class of graphs by generalizing prior notions of visibility, allowing the representing regions and sightlines to be arbitrary. We consider mainly the case of compact connected representing regions, proving two results giving necessary properties of visibility graphs, and giving some examples of classes of graphs that can be so represented. Finally, we give some applications of the concept, and we provide potential avenues for future research in the area.

1. INTRODUCTION

At the AMS/MAA Joint Meetings in San Antonio in January of 1999, Alice Dean presented a paper on rectangle-visibility graphs. A graph is defined to be a rectangle-visibility graph if there exists a set of closed rectangles on $\mathbb{R}^2$, with sides parallel to the coordinate axes and disjoint except possibly for overlapping boundaries, such that each vertex corresponds to a rectangle and two vertices are joined by an edge if and only if there exists an unobstructed horizontal or vertical corridor of positive width connecting the two corresponding rectangles [4]. There are many other concepts of visibility graphs; two of the most commonly used are the line-segment definition ([8], [3]) and the simple polygon definition ([1], [9]).

In this paper, we consider visibility graphs corresponding to an extended notion of visibility. Namely, we define a **sightline** to be a line segment between points in two different regions intersecting no other region. A graph G (all graphs we consider will be finite and simple) is then defined to be a **visibility graph** if there exists a set of disjoint nonempty connected regions in $\mathbb{R}^2$, with each region corresponding to a vertex of G , such that two vertices are connected by an edge in G if and only if there exists a sightline between the corresponding regions. Throughout this paper, we will identify vertices with the regions representing them.

Note that the regions are required to be connected. If we do not make this requirement, all connected graphs turn out to be visibility graphs by means of a simple construction. Let G be an arbitrary connected graph; order the vertices $v_1, \dots, v_n$ so that for all $1 \leq k \leq n$, the induced subgraph $G|_{v_1, \dots, v_k}$ is connected. Start with a disk representing v_1 . For each v_i in ascending order of i , cut a disk out of each area labeled v_j for all $j < i$ such that v_j and v_i are adjacent in G . Label the interior of this disk v_i . It is then straightforward to check that this yields a visibility representation of G , as illustrated in Figure 1.

By requiring the representing regions to be connected, we eliminate trivial constructions of this nature. In addition, we can require our representing regions to have other properties such as openness, compactness, and convexity; each of these yields a different theory of visibility graphs. We can restrict the theory further by choosing our regions from a severely limited list of objects, such as rectangles, disks or even points. Naturally, with each restriction, the number of representable graphs decreases.

We will be concerned primarily with **compact visibility graphs**, graphs that can be represented as visibility graphs using compact connected subsets of $\mathbb{R}^2$. (A subset $S \subset \mathbb{R}^2$ is **compact** if and only if it is closed and bounded; this is equivalent to requiring every infinite sequence $x_1, x_2, \dots$

Date: February 1, 2008.

of points in S to have a convergent subsequence.) This restriction allows us to give and prove a necessary property of graphs in this class, while at the same time preserving enough flexibility to facilitate visibility representations for a wide range of graphs.

2. CONVEX COMPACT VISIBILITY GRAPHS

We begin by considering the case in which our representing regions are not only compact, but also convex. We define a graph to be a **convex compact visibility graph**, or if it can be realized as a visibility graph in $\mathbb{R}^2$ with all representing regions both compact and convex. One of our main theorems is the following, which gives a necessary condition on such graphs.

Theorem 1. *If G is a convex compact visibility graph, then every edge of G must be either a bridge or part of a K_3 .*

The following lemma will be useful in the proof of the theorem.

Lemma 1. *Suppose we have mutually visible regions A and B . If any other region intersects a segment joining a point of A and a point of B , then the edge AB is part of a K_3 in the corresponding visibility graph.*

Proof. Take $a, a' \in A$ and $b, b' \in B$ so that $\overline{ab}$ is a sightline and $\overline{a'b'}$ intersects some other region. We have two cases: either $\overline{ab'}$ is a sightline or it is not. It suffices to consider only the second case; if $\overline{ab'}$ is a sightline, then switching the labels of the regions A and B and replacing (a, b, b') by (b', a, a') puts us in the situation of the second case.

Consider the straight line path $\phi : [0, 1] \rightarrow B$ from b to b' ; as B is convex, the image of this path lies entirely in B . Because all representing regions are compact, for any given region C intersecting some sightline $a\phi(t)$ there exists some minimal value t_C with $a\phi(t_C)$ intersecting C before B . (Note that if one such line intersects C before B , all such lines that intersect C must do so before B , as B and C are convex.) Since $\overline{a\phi(1)}$ is occluded, at least one such interloping region exists. Pick the region C with t_C minimal, so that $\overline{a\phi(t)}$ is unobstructed for $t < t_C$; if more than one such region exists, pick the one closest to a along the line $\overline{a\phi(t_C)}$. Call the first point of obstruction c . Then A is adjacent to C via the sightline $\overline{ac}$. Furthermore, each point on $\overline{cb}$ lies on $\overline{a\phi(t)}$ for some $t < t_C$ and thus must be unobstructed by the definition of t_C . Therefore, C is also adjacent to B via the sightline $\overline{cb}$, and so the edge AB is part of the triangle ABC . $\square$

We now proceed to the proof of Theorem 1.

Proof of Theorem 1. Let A and B be mutually visible regions in a convex compact visibility representation of G . Because A and B are compact convex regions, we can find common external tangent lines ℓ_1 and ℓ_2 to A and B . Let a_i (respectively, b_i) be a point in the intersection of A (respectively, B) and ℓ_i , as shown in Figure 2. If any other region contains a point in the closed region bounded by A , B , and these two tangent lines, then this point blocks some sightline between A and B . Therefore, we can apply Lemma 1 to conclude that the edge corresponding to AB is part of a triangle.

We may assume, therefore, that no such region exists. If every other region is contained either in the area bounded by A , ℓ_1 , and ℓ_2 (and on the opposite side of A from B) or that bounded by B , ℓ_1 , and ℓ_2 , it is clear that AB must be a bridge. Otherwise, we have one of two cases:

Case 1. Some region has nontrivial intersection with both some ℓ_i and the open half-plane on the opposite side of that line from A and B .

Without loss of generality, we may assume that this line is ℓ_1 , and that the region intersects ℓ_1 on the opposite side of A from B .

Let C be the first such region encountered by traveling along ℓ_1 from A away from B . Because C extends at least to ℓ_1 , we can construct, as in Figure 3, a sequence of points $\{c_i\}$ in C so that $\{c_i\}$ converges to $c \in C \cap \ell_1$, and each point c_i is on the opposite side of ℓ_1 as A and B .

Now, let D be any region besides C that intersects the open half-plane on the other side of ℓ_1 from A and B . Then D will not intersect the segment $\overline{cb_1}$ by our choice of C . Since D and $\overline{cb_1}$ are compact sets, the distance δ_D between them is positive; let δ be the smallest such δ_D . Then, if we pick i large enough so that $d(c_i, c) < \delta$, the sightlines $\overline{c_i a_1}$ and $\overline{c_i b_1}$ must be unobstructed. Thus ABC is a triangle.

Case 2. No such region exists; therefore, some region must lie entirely on the opposite side of some ℓ_i from A and B .

We may suppose without loss of generality that this line is ℓ_1 . Consider the set of all regions D_i lying on the opposite side of ℓ_1 from A and B . Since each region is compact, and does not intersect ℓ_1 itself, each has some minimum distance $\delta_i > 0$ to ℓ_1 . Choose a region D with minimum distance δ , and let $d \in D$ be such that $d(d, \ell_1) = \delta$. Now, consider the sightlines $\overline{da_1}$ and $\overline{db_1}$. These sightlines, which lie entirely on the opposite side of ℓ_1 from A and B , must be unobstructed, for any intervening region E would necessarily have $d(E, \ell_1) < \delta$. Therefore DAB is a triangle.

Thus, in both cases, the edge AB is part of a triangle. This completes the proof of the theorem. $\square$

The basic concept used in the proof of Theorem 1 is the division of $\mathbb{R}^2$ into three areas: the convex hull of $A \cup B$, the area blocked from A by B or from B by A , and the remainder. Using this division, we showed that if any region C intersects either the first area or the third, then AB is part of a triangle, and if no such region exists then AB is a bridge. This division and the proof carry through in the case where the representing regions are not required to be convex. The details are similar to those of the proof of Theorem 1, though slightly more technical, and are left to the reader.

Theorem 2. *If G is a compact visibility graph, then every edge of G is either a bridge or part of a K_3 .*

In light of this result, one might wonder whether or not the property of convexity is irrelevant to the set of representable graphs; that is to say, whether all compact visibility graphs are compact convex visibility graphs. However, Figure 4 shows an example of a graph that is a compact visibility graph, but not a convex compact visibility graph.

One might also wonder whether the converse of Theorem 2 is true, that is, whether or not every graph satisfying the conclusion of Theorem 2 is a compact visibility graph. This is easily shown to be false, however. To construct a counterexample, we make use of the following lemma.

Lemma 2. *Suppose that G is a visibility graph of any type, and v is a vertex all of whose neighbors are pairwise adjacent in G . Then $G - \{v\}$ is a visibility graph of the same type. (By **type** of a visibility graph, we mean a type of restriction on the allowable regions in its representation.)*

Proof. Construct a visibility representation of G , and remove the region corresponding to v . Consider any edge AB in the resulting visibility graph, with corresponding sightline $\overline{ab}$. If we consider $\overline{ab}$ in the original representation, the only region that can possibly block it is the region corresponding to v . However, if this is the case, then A and B are each connected to v using subsegments of $\overline{ab}$ as sightlines, so, by the hypothesis, A and B are adjacent in the original graph. Furthermore, if v does not block $\overline{ab}$ then A and B are certainly adjacent in the original graph. Thus the edge AB also occurs in $G - \{v\}$. Clearly $G - \{v\}$ is also a subgraph of the resulting visibility graph, so the two are identical, and the lemma is proven. $\square$

Now, consider the graph G shown in Figure 5, which satisfies the conclusion of Theorem 2. Suppose G were a compact visibility graph; by Lemma 2, we could then remove the four outside vertices to obtain a representation of C_4 using compact regions. However, no such representation exists (as C_4 does not satisfy the conclusion of Theorem 2), and so G cannot be a compact visibility graph.

In the proof of Lemma 2, we made explicit use of the geometry of the visibility representation of G . Indeed, the geometry of this representation yields a condition on the graph itself, as shown in the following theorem.

Theorem 3. *Suppose that there exists a convex compact visibility representation of G such that two sightlines $\overleftrightarrow{ab}$ and $\overleftrightarrow{vw}$ intersect, with a, b, v, w contained in distinct regions A, B, V, W . Then the vertices A and B are part of a K_4 inside G .*

Proof. If the regions A and B are both contained in the line $\overleftrightarrow{ab}$, or if either region is a point, the proof is fairly straightforward and is left to the reader. Suppose not; then, without loss of generality, there exists some point $a_0 \in A$ not on $\overleftrightarrow{ab}$.

We define a point $a' = (1 - \alpha)a + \alpha a_0$, where $\alpha < 1$ is sufficiently small that $\overleftrightarrow{vw}$ still crosses $\overleftrightarrow{a'b}$ and $\overleftrightarrow{a'b}$ is still a sightline. (If this latter condition were impossible, we could construct a sequence of points in some other region converging to $\overleftrightarrow{ab}$, and thus $\overleftrightarrow{ab}$ would also not be a sightline.) We furthermore require that B not be contained in the line through a' and b .

Now, we have $\overleftrightarrow{a'b}$ not tangent to A , and thus for b' sufficiently close to b we have $\overleftrightarrow{a'b'}$ not tangent to A . Pick $b_0 \in B$ not on the line $\overleftrightarrow{a'b}$. Then, take $b' = (1 - \beta)b + \beta b_0$, where β is sufficiently small that $\overleftrightarrow{a'b'}$ is a sightline and crosses $\overleftrightarrow{vw}$, and so that the line $\overleftrightarrow{a'b'}$ is not tangent to A . Then $\overleftrightarrow{a'b'}$ is tangent to neither A nor B , for it has points from both regions on either side of it.

Because of this construction, we can assume without loss of generality that our extended sightline $\overleftrightarrow{ab}$ is tangent to neither A nor B .

Let $\delta > 0$ be the minimum distance between any pair of regions; these distances are well-defined, as all regions are compact. For any line segment $\overline{jk}$, let $f(\overline{jk})$ be the length of the projection of $\overline{jk}$ onto a line perpendicular to $\overleftrightarrow{ab}$, and $g(\overline{jk})$ be the length of the projection of $\overline{jk}$ onto a line parallel to $\overleftrightarrow{ab}$; then f and g are always non-negative. Let $x = \inf\{f(\overline{jk})\}$, where the infimum is taken over all sightlines $\overline{jk}$ (between regions besides A and B) intersecting $\overleftrightarrow{ab}$. It is a simple consequence of compactness and the non-tangency of $\overleftrightarrow{ab}$ to A and B and compactness that we have $x > 0$.

Now, since the regions are compact and the line $\overleftrightarrow{ab}$ is tangent to neither A nor B , we can pick θ be sufficiently small so that a line drawn from a (respectively b) at an angle at most θ from $\overleftrightarrow{ab}$ must intersect B (respectively A) before any other region. Pick $\varepsilon > 0$ so that $\varepsilon < \delta \sin \theta$. Let $\overline{cd}$ be a sightline crossing $\overleftrightarrow{ab}$ with $f(\overline{cd}) < x + \varepsilon$, and let C and D be the regions containing c and d respectively. We claim that $ABCD$ is a K_4 in G . To verify this claim, we establish the existence of edges CA , CB , DA , and DB .

Let K be the triangle cad in the plane, and consider the visibility graph H defined by the regions $\{X \cap K\}$, where X ranges over all the regions intersecting K from our original visibility representation of G ; see Figure 6. As K is convex, and all of these new regions are contained in K , all relevant sightlines will also be contained in K ; furthermore, H is clearly a subgraph of G . Now, H is a visibility graph, and CD is an edge of H . By Theorem 1, we know that CD is either a bridge or part of a triangle.

Since c and d are on opposite sides of the unobstructed sightline $\overleftrightarrow{ab}$, no region besides A can intersect both $\overline{ca}$ and $\overline{ad}$. Taking the sequence of regions encountered along $\overline{ca}$ gives a path from C to A in the graph H , and similarly taking the sequence of regions along $\overline{ad}$ gives a path from A to D . Composing these yields a path from C to D not including the edge CD , since D cannot appear

in the first part (as it appears in the second), and C cannot appear in the second. Consequently, removing the edge CD cannot disconnect the graph H , so CD cannot be a bridge in H .

Therefore, CD must be part of a triangle in H , so there must exist some region E with both CE and DE edges of H . Unless $E = A$, E must lie either entirely above the unobstructed sightline $\overline{ab} \cap K$ or entirely below it. However, if E lies above this line, the sightline $\overline{d'e}$ corresponding to the edge DE crosses $\overline{ab}$. Furthermore, as $e \in K$ and the distance from e to c is at least δ , it follows from our choice of ε that $f(\overline{d'e}) < x$, a contradiction. Similarly, E cannot lie below $\overline{ab} \cap K$, as then $f(\overline{c'e}) < x$. Consequently, E must be the region A , so that both of the edges CA and DA occur in H and, therefore, in G . Interchanging A and B shows that the edges CB and DB must also occur in G , so that $ABCD$ forms a K_4 as desired. $\square$

Theorem 3 rules out an additional class of graphs, and places constraints on possible representations of many more graphs. Noting that if a visibility representation has no crossing sightlines, the corresponding graph is planar, we obtain the following corollary.

Corollary 1. *Every convex compact visibility graphs either is planar or contains a K_4 .*

An example of a graph that this corollary excludes from being a convex compact visibility graph is shown in Figure 7.

3. EXAMPLES OF COMPACT VISIBILITY GRAPHS

Theorem 2 shows that many simple graphs are not compact visibility graphs; in particular, C_n is not a compact visibility graph for $n > 3$. Furthermore, it is easy to check that every nonempty compact visibility graph must be connected. Nevertheless, we can construct large families of compact visibility graphs.

Theorem 4. *If G has a plane drawing such that all of the internal faces are triangles, then G is a compact visibility graph.*

Proof. Assume first that G has no cut vertices, that is, vertices v such that $G - \{v\}$ is disconnected. We start with a plane drawing of G , which we may assume has convex boundary face, and construct from this drawing a compact visibility representation of G . Consider any edge vw . We break vw at an arbitrary point in its interior, and interlace the two halves of vw together at this point, as shown in Figure 8. We then take as the representing region for v the union of all the half-edges containing v . It is clear that every edge vw corresponds to a sightline; furthermore, every sightline lies entirely in the interior of some face of the drawing, and thus only connects regions corresponding to the vertices of this face. As these vertices form a K_3 in the graph, there are no extraneous edges added, and so this assignment of regions shows that G is in fact representable as a visibility graph.

In the case where G has a cut vertex v , we can split the vertex as in Figure 9 and then represent the resulting graph as a visibility graph as before, except that we do not do the above for the edge v_1v_2 . This yields a representation of G as a visibility graph. $\square$

A simple corollary of Theorem 4, as every tree has a plane drawing with no internal faces, is the following.

Corollary 2. *All trees can be represented as compact visibility graphs.*

In fact, all trees are convex compact visibility graphs, or even compact disk visibility graphs.

Since C_n is not a compact visibility graph for $n > 3$, one might suspect that a planar graph G is a visibility graph if and only if it has a plane drawing such that all of the internal faces are triangles. This, however, turns out to be false. Consider the case of $K_{1,1,n}$. This is easily seen to be a compact visibility graph (as in Figure 10), but it is a planar graph with no such drawing for

$n \geq 3$. The key point here is that the induced subgraph on the four-sided face is not C_4 ; given this, we conjecture that the following modification of the converse holds.

Conjecture 1. *A planar graph G is a compact visibility graph if and only if it has a plane drawing such that for all internal faces F of G , the subgraph G_F induced by the vertices of F is a compact visibility graph.*

4. THE NON-COMPACT CASE

Throughout the previous two sections of this paper, we have assumed that our representing regions are compact. In this section, we give our rationale for this assumption, as well as some comments about the non-compact theory.

Theorem 2 does not hold in the non-compact case. Indeed, the cycles C_n are visibility graphs, as shown by the two representations in Figure 11.

Furthermore, if we eliminate the hypothesis of compactness, we can even realize disconnected graphs as visibility graphs. Let A be the set $\{(x, y) \mid 0 < x \leq 1, y = \sqrt{x} \sin \frac{1}{x}\}$, B be the set $\{(x, x + y) \mid (x, y) \in A\}$, and C be the single point $(0, 0)$, as represented in Figure 12. Then the only unblocked sightlines are between A and B , and so $\{A, B, C\}$ is a visibility representation of a disconnected graph.

Combining the technique of interlacing presented in Figure 12 with the second method for realizing C_n presented in Figure 11, we can realize any connected planar graph as a visibility graph. Given a face F , for each vertex v we construct in the interior of F interlocking spirals $s_{v,F}$, each having infinitely many turns; one of these spirals is shown in Figure 13. The region corresponding to v then consists of the union over all faces F containing v of the spirals $s_{v,F}$.

While it is not true that we can represent any graph as a visibility graph (consider the case of two isolated vertices), the fact that all connected planar graphs can be realized as visibility graphs leads to the following conjecture:

Conjecture 2. *Any connected graph is representable as a visibility graph.*

5. SETTINGS OTHER THAN $\mathbb{R}^2$

It is natural to extend the concept of visibility graphs to higher-dimensional Euclidean spaces. Specifically, one might consider the case of $\mathbb{R}^3$. Analogues to rectangle-visibility graphs exist in $\mathbb{R}^3$; in particular, Fekete and Meijer [6] consider the question of which complete graphs are representable as box-visibility graphs. Alternatively, one can require that the sightlines be strictly vertical, and that each representing set lies in a horizontal plane; the question of such representations has been considered by Alt, Godau, and Whitesides [2].

In $\mathbb{R}^3$, Conjecture 2 is true (using our notion of visibility). Let T be a spanning tree for an arbitrary connected graph G ; using the construction shown in Figure 1 with spheres instead of circles, we first construct a visibility representation of T . Then, to add an edge between two vertices V and W , we pick any points $v \in V$ and $w \in W$, and remove all points on the interior of the line segment $\overline{vw}$. It is clear that this will only add the single sightline from V to W , as the line has thickness 0 and all representing regions have positive thickness. Unlike in the two-dimensional case, this construction does not disconnect any regions. After all remaining edges of G have been added in this fashion, one is left with a visibility representation of G .

In the compact case, we have results similar to those in $\mathbb{R}^2$. With only slight modifications, the proof of Theorem 2 carries over into $\mathbb{R}^n$, so that Theorem 2 is true in general Euclidean spaces. This suggests the following two questions.

Question 1. *Is it true that all graphs representable as compact visibility graphs in $\mathbb{R}^3$ are also representable as compact visibility graphs in $\mathbb{R}^2$?*

Question 2. *Does there exist a positive integer n such that all graphs representable as compact visibility graphs in any Euclidean space are representable as compact visibility graphs in $\mathbb{R}^n$?*

Two other venues to which visibility graphs generalize easily are the torus T^2 and the sphere S^2 ; Mohar and Rosenstiehl [7] briefly considered the former case with restricted sightlines. In order to make sense of the general concept, we must define the notion of a straight line in both settings. We define straight lines on the torus by considering it as the quotient space $\mathbb{R}^2/\mathbb{Z}^2$; on the sphere, we take the straight lines to be the ordinary geodesics. Which graphs are representable as visibility graphs in these new settings?

6. CONCLUSION

The generalized concept of a visibility graph lends itself to various applications. Since the set of representing regions contains all of the information about the graph itself, it can be used as an encoding of information about the n vertices of a graph G and the $\binom{n}{2}$ connectedness relations into a set of n objects. If we require the representing regions to be disks, we have this information using $3n$ coordinates: one triple (x, y, r) for each disk.

Visibility graphs also can be used naturally to represent various kinds of networks. For instance, consider a network of army bases on a battlefield that communicate with each other via torch signals (or, if you will, lasers). The graph of this network will then be the visibility graph represented by the layout of the bases. Similarly, on a more global scale, one may wish to manipulate the situation so that one can communicate in this fashion with one's allies and at the same time intercept lines of communication between one's enemies. In this latter case of two rival alliances, it is appropriate to partition the vertices into two classes, and only consider sightlines between two regions of the same class; what pairs of networks can be realized in this fashion? The concept of visibility graphs provides a natural representation of graphs in $\mathbb{R}^2$ that can be used to examine these questions.

ACKNOWLEDGEMENTS

The authors would like to thank Alice Dean for presenting the original talk which spurred the work presented in this paper, and Joseph Gallian for helpful comments on a preliminary version of it; we would also like to thank the referees for their suggestions. The first two authors were financially supported by the University of Minnesota-Duluth and grants from the National Science Foundation (Grant DMS-92820179) and the National Security Agency (Grant 904-00-1-0026), and by NSF Graduate Research Fellowships. The third author was supported by the University of Wisconsin and the Center for Communications Research in Princeton.
